Abstract

Aim: To assess the safety, feasibility and efficacy of ^{125}I seeds irradiation stents compared with conventional self-expandable metal stents (SEMS) to treat malignant obstructive jaundice (MOJ).**Methods:** A systematic search of English and Chinese databases, from January 1980 to December 2017, was conducted. All prospective random trials comparing SEMS and the various form of irradiation stent with ^{125}I seeds to treat MOJ were included.**Results:** Overall, six studies with 276 patients were eligible in current analysis. Of reported 276 patients, 138 patients were subjected to irradiation stents while 138 patients to SEMS. The irradiation stents are associated with a longer survival (hazard ratio (HR) 0.46, IV, random, 95% confidence interval (CI) 0.34-0.63; $p < 0.001$, $I^2 = 0\%$) and stent patency (HR 0.45, IV, random, 95% CI 0.25-0.80; $p = 0.007$, $I^2 = 59\%$) than conventional SEMS.There are no differences in total complications rate (relative risk (RR) 0.75, M-H, random, 95% CI 0.41-1.38; $p = 0.35$, $I^2 = 0\%$), hemobilia (RR 0.34, M-H, random, 95% CI 0.07-1.64; $p = 0.18$, $I^2 = 0\%$), pain (RR 0.87, M-H, random, 95% CI 0.29-2.61; $p = 0.80$, $I^2 = 0\%$), and cholangitis (RR 1.33, M-H, random, 95% CI 0.32-5.48; $p = 0.69$, $I^2 = 0\%$).Also, no differences were observed in all indexes, which included total bilirubin (TBIL) (weighted mean difference (WMD) -5.52, IV, random, 95% CI -20.58-9.54; $p = 0.47$, $I^2 = 33\%$), direct bilirubin (DBIL) (WMD 7.38, IV, random, 95% CI -8.00-22.75; $p = 0.35$, $I^2 = 0\%$), alanine aminotransferase (ALT) (WMD 2.76, IV, random, 95% CI -14.05-19.57; $p = 0.75$, $I^2 = 64\%$), aspartate aminotransferase (AST) (WMD 9.49, IV, random, 95% CI -9.31-28.29; $p = 0.35$, $I^2 = 0\%$).**Conclusions:** According to limited source data, the current meta-analysis suggests that the irradiation stent is a feasible, safe treatment of MOJ, with longer survival and

stent patency. Application of irradiation stent with anti-tumor effect does not add extra adverse events compared to SEMS stent.

Keywords: ^{125}I seeds; Malignant obstructive jaundice; Choledochojejunostomy; Stent patency

Introduction

Malignant obstructive jaundice (MOJ) is a common clinical disease entity primarily caused by pancreato-biliary malignancies including cholangiocarcinoma, pancreatic cancer and ampullary cancer [1,2]. At the time of diagnosis, majority of patients have been barred from radical resection due to extensive tumor growth [3,4].

The median survival of patients with MOJ is reported as 4.8 months [5]. Alleviation of patients' clinical symptoms and correction of complications are priority regarding its unimproved and limited survival and quality of life [2,5].

During recent three decades, surgeons and interventional therapists endeavored to perform palliative drainage by means of choledochojejunostomy, laparoscopic or open, endoscopic or percutaneous techniques [6]. Biliary stents showed better clinical efficacy and quality of life compared to surgical bypass [7].

Various types of biliary stents with special structure and materials were designed for endoscopy or percutaneous drainage. Previous studies compared different types of stents and claimed that self-expandable metallic stents (SEMS) is superior to plastic stents in terms of patency, morbidity, and re-interventions [8].

In addition, no obvious advantages were identified in covered self-expandable metal stent (CSEMS) or uncovered self-expandable metal stents (UCSEMS) [9]. However, the tumor growth is not control and resulting in a high risk of occlusion, epithelial hyperplasia, sludge formation, and clot accumulation [10,11].

Efforts have been made to introduce novel biliary stent with anti-tumor effect. Currently, paclitaxel-eluting stents [12] and irradiation stent loaded with ^{125}I seeds [13-18] are among the mostly used stents in South Korea and China respectively.

Permanent radioactive seed implantation in malignancy was firstly suggested by several authors in the early 1900s [19]. Thereafter, this technique has been practiced in different types of cancers. Recent years, large number of animal experiments, single arms, and control studies regarding the application of ^{125}I stent in patients with MOJ have been published one after another [20,21].

However, systematic review and meta-analysis comparing ^{125}I stents with conventional stents are still lacking. Therefore, we performed a systematic review and meta-analysis by synthesizing present evidence to assess efficacy and safety of the irradiation stents compared with conventional stents.

Materials and Methods

Eligibility criteria

We include all randomized controlled trials (RCTs) and control clinical trials (CCTs) in human. There were no language restrictions. Conference abstract and thesis were ruled out. We included single and multi-centre studies, which compared the ^{125}I irradiation stent (various form of combined implantation of ^{125}I seeds and CSEMS or UCSEMS) with CSEMS or UCSEMS.

Both endoscopic and percutaneous approaches for stent implantation were included. The study population is without age and gender restrictions. MOJ was caused by any unresectable tumor (distal or proximal).

Search strategy

English databases (MEDLINE, EMBASE, Cochrane library), Chinese databases (CBM, CNKI, VIP), and Clinicaltrials.gov (from January 1980 to December 2017) were searched. References of systematic review and included studies were also searched. The search strategy was based on MeSH terms combined with text words. The detail can be view in **Table S1**.

Choice of outcome

The primary outcomes included patient survival and cumulative stent patency. Cumulative stent patency is time from stent placement to recurrent biliary obstruction or patient died.

Secondary outcomes included (i) complications: total complications, pancreatitis, cholecystitis, cholangitis, hemobila, stent and seed migration, tumor ingrowth and outgrowth; (ii) post-operative laboratory values: alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TBIL), direct bilirubin (DBIL).

Data collection

Two independent reviewers (S.A and L.Y.P) selected the studies by reviewed the title and abstract of every single study. Disagreements were resolved by a third reviewer (T.T). For selected studies, data of trial information (author, year, intervention, center and type of stent), population characteristics (sex, age, classification of the tumor and location of obstruction), and reported outcomes were extracted independently by two investigators (H.Z and S.A).

Quality of studies was assessed by the Cochrane Collaboration's tool for assessing risk of bias. The assessment was carried out by three independent investigators (H.Z, T.T and S.A).

Statistical analysis

Hazard ratios (HRs) with 95% confidence intervals (CIs) were chosen to measure the effects of stent patency and patient survival, relative ratios (RRs) with 95% CIs to measure the complications, and weighted mean differences (WMDs) to measure laboratory values. HRs can be extracted from the paper directly or obtained by method of Tierney et al. [22] from Kaplan-Meier curves or other data.

All comparisons were performed by random-effects models in RevMan software version 5.3. Inconsistency index (I^2) statistics were calculated to measure the heterogeneity. Although size of heterogeneity have no uniform definition, I^2 values more than 50% indicated significant heterogeneity in current article. Sensitivity analyses were performed, if high heterogeneity was found or the significance of effect size was affect by a single study. For primary outcome, publication bias was assessed using Egger test and Begg test by Stata 14.0.

Results

Search results

A total number of 1120 publications were examined in initial systematic search. 1098 duplicates and irrelevant comparisons publications were excluded. Of remaining 22 trials, seven were single arm studies, six were retrospective studies, eight were theses and conference abstracts, four were duplicate publications.

Finally, six studies (**Tables 1 and 2**) were included in the meta-analysis with three English articles [13,15,18] and three Chinese articles [14,16,17]. English abstract of Chinese article can be searched in PubMed or EMBASE, one was registered in clinicaltrial.com. The prisma flow is shown in **Figure 1**.

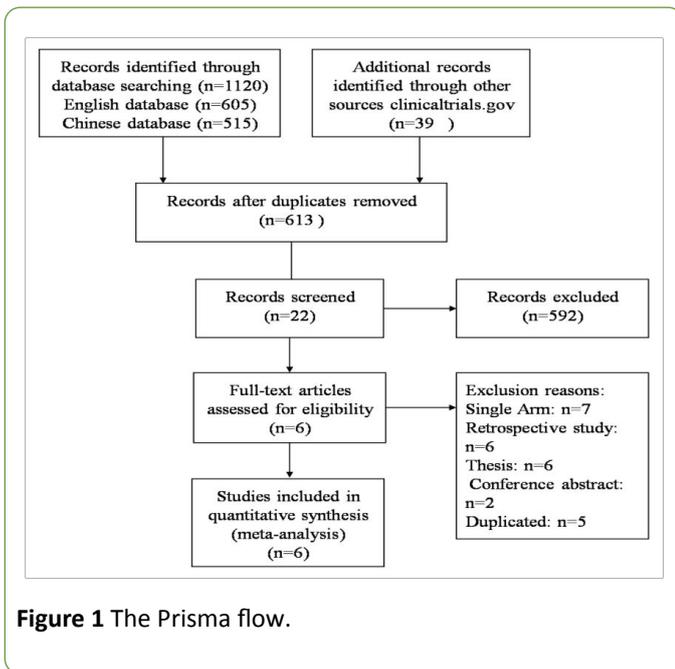

Figure 1 The Prisma flow.

A total of 276 patients were enrolled, 138 to irradiation stents and 138 to UCSEMS. Cholangiocarcinoma and pancreatic cancer were the main reasons for MOJ. In all studies, stent and ¹²⁵I seeds implantations was performed by percutaneous insertion and UCSEMS was identified as control group. All studies were carried out by single center in China.

Risk of bias

Six trials included three RCTs and three CCTs. Every study was conducted a qualitative risk assessment by Cochrane Collaboration’s tool for assessing risk of bias (Figures S1 and S2). Performance bias was severe, due to it is difficult to mask radiologists on whether to implant radiation sources. High heterogeneity was observed in comparisons of stent patency and ALT.

Table 1 Characteristics of the studies included in meta-analysis.

| Study | Stent | NO. of patients | Male/female | Age (y) | patient survival (days) | stent patency (days) | No. of complications |
|-------------|--------------------|-----------------|-------------|------------------------|-------------------------|-----------------------|----------------------|
| Hasimu [15] | Irradiation stents | 28 | Nov-17 | mean ± SD 70.93 ± 8.58 | mean ± SD 222.6 ± 21.0 | mean ± SD 191 ± 19.8 | 4 |
| | UCSEMSs | 27 | 14/13 | mean ± SD 70.26 ± 9.71 | mean ± SD 139.1 ± 14.5 | mean ± SD 88.3 ± 16.3 | 5 |
| Zhu [18] | Irradiation stent | 12 | 07-May | Median 62.50 (21.00) | median 222 | median 222 | 1 |
| | UCSEMSs | 11 | 09-Feb | Median 71.00 (22.00) | median 75 | median 75 | 5 |

| Total | - | 171 | 6 | 37 | 31 | 10 | 9 |

Sensitivity analyses were carried out, no differences were observed in any comparisons. Heterogeneity of stent patency originates from CCTs.

After excluding the trial, heterogeneity decreased distinctly, but the outcome was the same indicated that irradiation stents exhibited a better stent patency.

The Egger and Begg tests were carried out to assess potential publication bias for primary outcomes, and no potential publication biases were observed (Figure S3).

Primary outcomes

Patient survival: Patient survival data were not provided in one study. The statistical data of five studies revealed significantly favorable to irradiation stents at patient survival (HR 0.46, IV, random, 95% CI 0.34-0.63; p<0.001, I²=0%) (Figure 2).

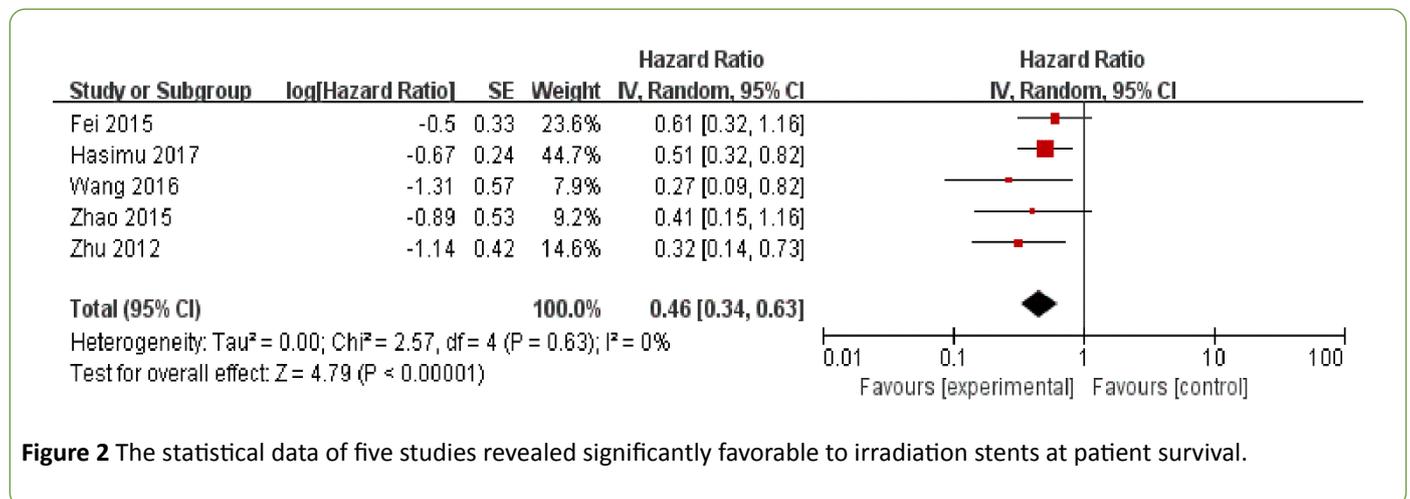

Figure 2 The statistical data of five studies revealed significantly favorable to irradiation stents at patient survival.

Stent patency: The meta-analysis from the 4 studies revealed significantly favorable to irradiation stents at stent

patency (HR 0.45, IV, random, 95% CI 0.25-0.80; p=0.007, I²=59%) (Figure 3).

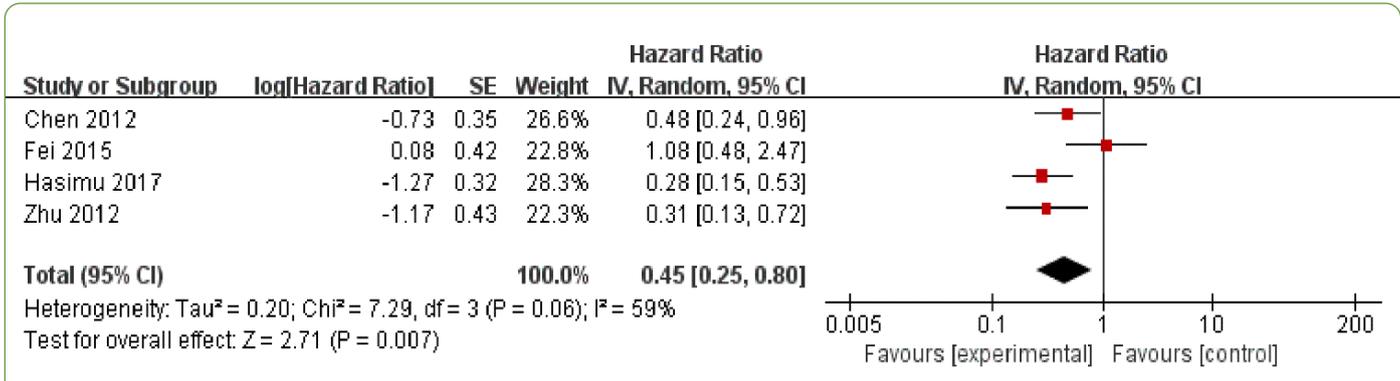

Figure 3 The meta-analysis from the 4 studies revealed significantly favorable to irradiation stents at stent patency.

Secondary outcomes

Complication rate: There are no differences in total complications rate (RR-0.75, M-H, random, 95% CI 0.41-1.38;

p=0.35, I²=0%), hemobilia (RR 0.34, M-H, random, 95% CI 0.07-1.64; p=0.18, I²=0%), pain (RR 0.87, M-H, random, 95% CI 0.29-2.61; p=0.80, I²=0%), and cholangitis (RR 1.33, M-H, random, 95% CI 0.32-5.48; p=0.69, I²=0%) (**Figure 4**).

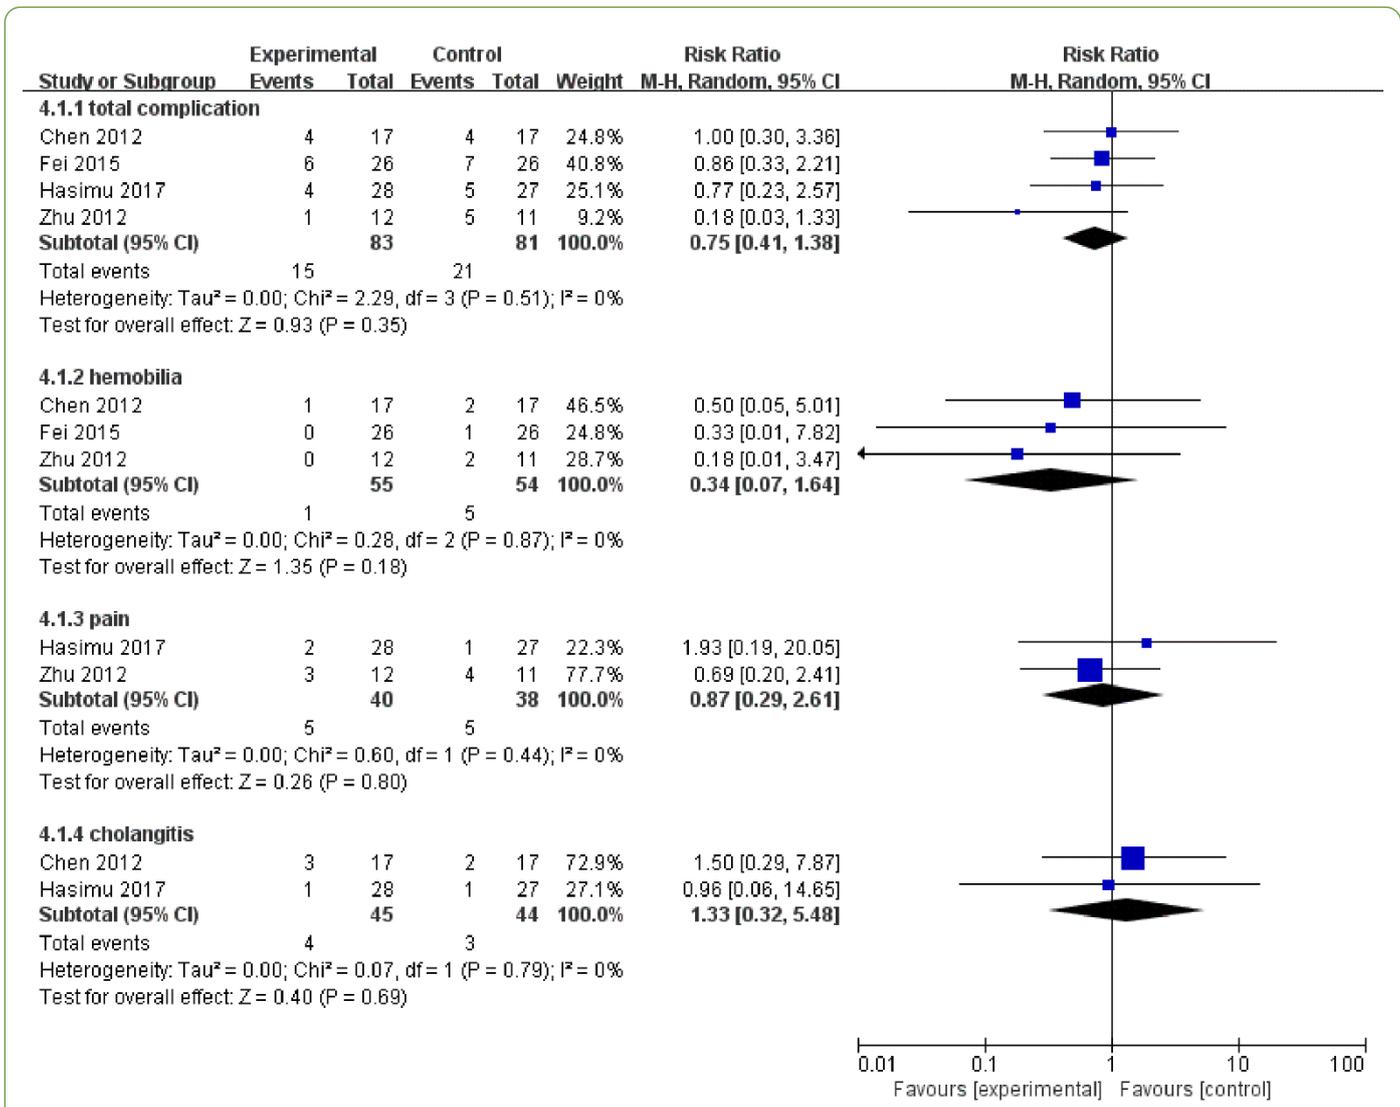

Figure 4 Complication rate.

Post-operative laboratory index: No differences were observed in all indexes, which included to TBIL (MD -5.52, IV, random, 95% CI -20.58-9.54; p=0.47, I²=33%), DBIL (MD 7.38, IV, random, 95% CI -8.00-22.75; p=0.35, I²=0%), ALT (MD 2.76,

IV, random, 95% CI -14.05-19.57; p=0.75, I²=64%), AST (MD 9.49, IV, random, 95% CI -9.31-28.29; p=0.35, I²=0%) (Figure 5).

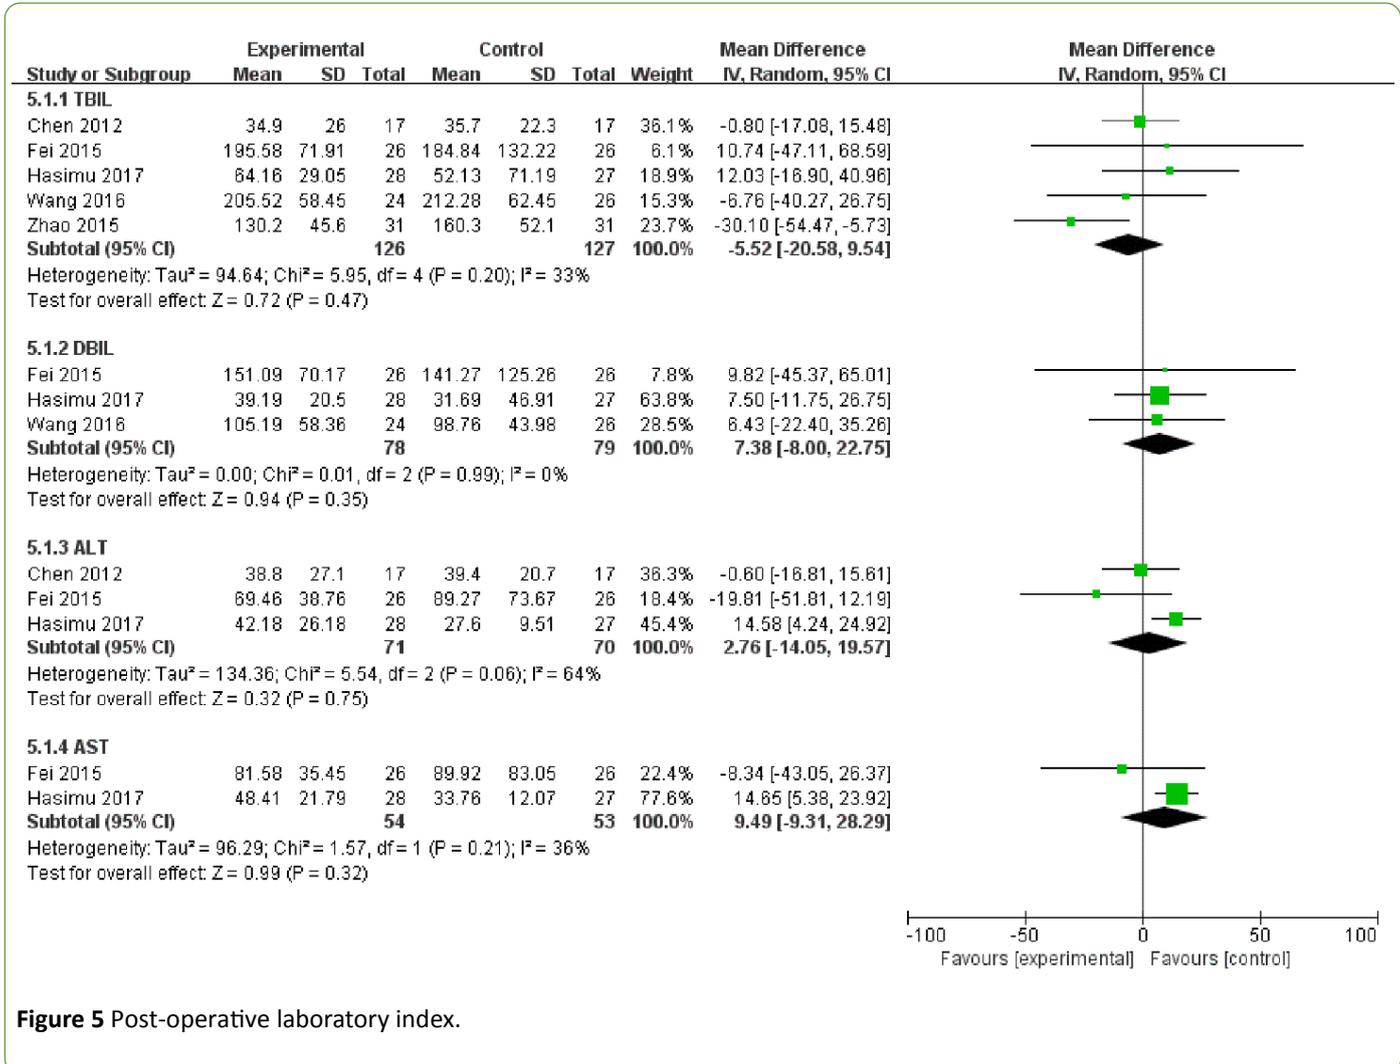

Figure 5 Post-operative laboratory index.

Discussion

Biliary stents have been applied in treatment of patients with MOJ more than 30 years, since it is considered as the most effective and mini-invasive approach to alleviate patients' clinical symptoms. Currently, local chemoradiotherapy combined with stent drainage has been becoming the classic therapeutic strategy to prolong patient survival and stent patency [6]. However, the hypovascular feature of pancreatic cancer, cholangiocarcinoma, and most of metastases limit curative effect of chemotherapy [23,24].

Additionally, the existence of radiosensitive organs around the site of obstruction and poor general conditions of patients may lead to adverse events in application of external beam radiation therapy. Intraluminal brachytherapy (ILBT) avoid these problems. Before Iodine-125, Iridium-192 wire as a high dose of irradiation showed promising effects in MOJ treatment [24,25]. However, with the development of radioisotope seeds, Iodine-125 seed as a low dose seed has been replacing Iridium-192 in many indications [26], due to the advantage of

safety and prolonged exposure which avoid the second operation to take out the seeds and/or repeated interventions in some conditions.

To the best of our knowledge, this is the first meta-analysis to assess the safety and efficacy of ¹²⁵I irradiation stent compared with conventional metal stents. The meta-analyses of primary outcome showed that irradiation stent provided significantly longer patient survival and stent patency. Same results can observe from median or mean of patient survival and stent patency which were not involved the meta-analysis, due to the limited expression of overall survival status.

Although there were various inserting ways and type of irradiation stents in different studies, all implanting seeds increased complexity of the operation and narrowed caliber of stent indirectly. However, our analyses showed no significant difference between two group in complication rates and laboratory values after operation which were analyzed to measure the short-term drainage efficiency and recovery of liver function. Three studies reported Hemobilia, which occurred mainly during hospital stay and were healed before

discharge, due to injury of the biliary intima resulted from the interventional operation rather than effect of irradiation. Fecal occult blood test in Chen et al. [13] indicated negative results in both groups during the first month of follow-up. The quantitative records of pain were defined as short-term and severe conditions, which were mainly caused by biliary irritation, operative injury, and infection. Two investigators have reported the incidence of cholangitis, although a previous study [27] suggested that ILBT correlates with increased risk for cholangitis, especially after percutaneous transhepatic biliary drainage (PTBD) or stent insertion, our analyses showed no significant difference between two groups, even carrying drainage catheter with the seeds strand for two months in the experimental group of Chen et al.

Three studies reported antitumor effect of irradiation stents. CA19-9 were followed up by two investigators [16,17] at different time points, the results showed after procedure the marker declined and remained at a lower level in experimental group, while the marker in control group was gradually increased. Fei et al. [14] showed the change in maximum and minimum tumor size before and six months after operation by CT scan. The results indicated that the seed strand shrank the tumor obviously.

In terms of radiological safety, a minimal average dose (0.018 ± 0.009 mSv) were detected in Liu et al. [21] by a personal dosimeter, which was worn on the waist of operator during all procedures. Additionally, the effective radiation radius of ^{125}I seeds is less than 20mm that results in easy radioprotection for peri-tumor tissue and medical workers [28]. The number and distribution of implanted seeds were determined by the length of the obstructive segment. In seeds strand, Fei et al. [14] identified a 6-10mm source-to-source distance to adjust radiation dose. However, other studies arranged no spacing in their seed strand. Tight arrangement provided higher dose (80-90Gy), which has been proven to be safe in the previous experiment [29]. And all studies mentioned no migration or dislodging of ^{125}I seed was observed during the follow-up period, also no radiation-induced enteritis or liver injury were reported.

In the current meta-analysis, as in previous clinical and animal studies, irradiation stent displayed better efficiency and has equal safety and stability compared with conventional stent. Although various forms of the irradiation stent with ^{125}I seeds have been used in treatment of MOJ and a number of clinic retrospective studies can be indexed, there are no guidelines for specific applications, uniformly designed stents, and experience of using radioactive source for the most of clinical department. Considering radioactivity, operators might prefer to other non-radioactive methods. Clearly, the wide application of irradiation stent in MOJ still has a long way to go, and need further promotion and more special stent and auxiliary equipment. Moreover, a recent high quality RCT [12] demonstrated another anti-tumor paclitaxel-eluting stent had no obvious advantage over the conventional covered stent. Nevertheless, maybe we can compose the two stent together to obtain better effectiveness, based on the radiosensitization of paclitaxel in many malignant tumors [30].

Limitations

The most important limitation of the current meta-analysis is only six studies were included into the analyses according to our inclusion criteria, and all studies are from Chinese single center. Owing to the limited number of studies, the power of publication bias tests was also reduced significantly. All studies were performed by percutaneous insertion and only used UCSEMS both in two groups. Sources of heterogeneity include patient populations (different department, other treatments during follow-up or not, proximal or distal), use of antibiotics, definitions of complications, choice of reporting secondary outcomes, and measures of data spread. The Cochrane bias risk score showed incomplete blind method, which caused by the nature of invasive procedures. Moreover, since most of the patients died during the follow-up period, there is not an appropriate index to measure the stent patency only, which also caused the differently reported form and made it difficult to integrate. Finally, no studies involved cost-effective analysis or mentioned the cost of seed strand and seeds-loaded-stent, which may limit the application of the results and choice of finished products or self-made seed strand.

Conclusion

Our meta-analysis suggested that various kinds of ^{125}I seeds irradiation stent are a potent tool for MOJ. The patients treated with the irradiation stent do not experience extra adverse events (pain, hemobilia, and cholangitis) and have a longer survival, stent patency, compared with UCSEMS. And the unique anti-tumor effect of irradiation stent was noted by CA19-9 and CT scan during the follow-up period.
